ARTICLE INFO

Keywords: Pool boiling Ammonia/Fe₃O₄ Nanofluid Molecular dynamics External force

ABSTRACT

Background: In this study, the pool boiling heat transfer of Fe₃O₄ /ammonia nanofluid in a copper (Cu) nanochannel is done using the molecular dynamics (MD) simulation.

Methods: To increase and improve the performance of heat transfer, the effect of external force, and external magnetic field frequency on the atomic and thermal performance of the simulated nanostructure was checked. The results show that the density increased with a positive slope when the external force was imposed on the nanostructure with a growing trend. The amount of velocity and temperature similarly increased. So, by increasing the external force from 0.001 to 0.005 eV/ \AA , the maximum values of density, velocity, and temperature converge to the values of 0.1441 atom/ \AA^3 , 13.939 \AA /fs, and 794.61 K. Moreover, increasing the applied external force caused an increase in the heat flux and thermal conductivity in the nanostructure. Finally, studying the effect of external magnetic field on the nanofluid's atomic behavior shows that with the change in the frequency of external magnetic field, Poiseuille behavior was remained. The results of the increase in the frequency of external magnetic field show the increasing trend of velocity and temperature. Numerically, the maximum values of velocity and temperature increase from 7.133 to 11.476 Å/fs, and from 210.23 to 410.07 K, respectively. Furthermore, HF increases by increasing the frequency of external magnetic field.

Significant findings: As particles' movement increased, the structure's thermal resistance decreased. So, by increasing external force, the thermal resistance in the structure decreased.

1. Introduction

At the same time as the climate crisis worsens, the world is investing in carbon-free energy to create a world where either the production of greenhouse gasses is zero or the same amount of greenhouse gas is emitted from the world's blow air $[1,2]$ $[1,2]$. There are various methods to reduce using the fossil fuels, such as using green hydrogen [\[3\]](#page-7-0) or alternative catalyst and fuel refrigerants [\[4\]](#page-7-0). Natural gas is one of the world's cleanest fossil fuels. Ammonia is a natural refrigerant compatible with the environment. This refrigerant has excellent thermodynamic and thermal properties. It is widely used in large refrigeration systems. It was used in industries, such as the refrigerators and air conditioners. Studying the biological and environmental effects of refrigerants (synthetic and natural) showed that in the long term, using the natural refrigerants in various refrigeration and air conditioning industries was recommended $[5,6]$ $[5,6]$ $[5,6]$. According to the heat transfer

characteristics of ammonia, this refrigerant is the most suitable for thermophysical properties [[7,8\]](#page-8-0). Today, the need for effective cooling in small systems was increased in terms of the advances in nanotechnology. The research shows that adding the nanoparticles improved the thermal behavior of different fluids due to having a higher conductivity coefficient than fluids. To be more precise, two main characteristics of nanoparticles are very high stability, and the other is a very high coefficient of thermal conductivity $[9-11]$ $[9-11]$. Also, previous studies show that applying a magnetic field can improve the performance of fluid inside the atomic duct [\[12\]](#page-8-0). Nanofluids that contain magnetic nanoparticles are widely used in various fields in terms of their higher heat transfer capabilities [\[13\].](#page-8-0)

Nanofluid heat transfer applications are very important and practical [[14,15](#page-8-0)]. Several studies were conducted in pool boiling heat transfer [16–[19\]](#page-8-0). Whenever the temperature of an object immersed in a liquid, such as the wall of a container, was higher than the saturation temperature of fluid associated with it, the phenomenon of pool boiling was observed $[20,21]$ $[20,21]$. The boiling process was characterized by forming steam bubbles separated from the hot surface after successive growth [\[22\]](#page-8-0). Bubble growth depended on excess temperature, surface material, thermodynamic properties of the fluid, and surface tension. On the other hand, steam formation and boiling on the surface were effective in the heat transfer [\[23](#page-8-0)–25].

For example, Wen et al. [\[26\]](#page-8-0) checked the thermal performance of pool boiling using Al_2O_3 and TiO₂ nanofluids. They showed a 40% improvement in critical HF. Moreno et al. [\[27\]](#page-8-0) studied the effects of nanoparticle size on critical HF using Al_2O_3 nanoparticles in the base fluid. Amiri et al. [\[28\]](#page-8-0) investigated the effect of nanoparticles to improve the critical HF. They used multi-walled carbon nanotubes (MWCNT) with different diameters. They found that the diameter of nanotubes affected the critical HF, and as the diameter of nanotubes increased, the amount of HF decreased. Kim et al. [\[29\]](#page-8-0) perused the effect of surface moisture on pool boiling heat transfer and critical HF with SiO_2 , ZrO_2 and Al_2O_3 . The results show that the critical HF increased to 80%, and the heat transfer coefficient was weakly improved. Vitarana et al. [\[30\]](#page-8-0) perused nanofluids' boiling heat transfer coefficients of Au-H₂O, SiO₂ - H₂O, and SiO₂-ethylene glycol in a cylindrical chamber. This research revealed the improvement of critical HF and heat transfer coefficients between 11% and 21%. Prag et al. [\[31\]](#page-8-0) investigated the pool boiling using nanofluids based on MWCNTs. Tlili et al. . [\[32\]](#page-8-0) examined the effect of channel dimensions on the thermal behavior of air in the presence of phase change materials. Dero et al. [\[33\]](#page-8-0) examined the thermal stability of water/copper-alumina nanofluid.

Due to solving and explaining many phenomena using laboratory methods was impossible or very expensive and time-consuming, today, it is possible to solve many problems using computational methods. For instance, Rajakarunakaran et al. [\[34\]](#page-8-0) examined the mechanical behavior of self-compacting concrete using numerical methods. The obtained results reveal that it predicts the mechanical behavior of studied structure well. Bai et al. [\[35\]](#page-8-0) examined the effect of concentration and graphene oxide nanoparticles on the thermal behavior of water/ graphene oxide nanofluid using different numerical methods. The results show that numerical methods could predict the studied structure's thermal performance. Banawas et al. [\[36\]](#page-8-0) examined the effect of initial temperature and pressure on the thermal and mechanical behavior of calcium phosphate cement using MD simulation. The results show that decreasing the temperature and increasing the pressure led to improving the thermal and mechanical stability of structure. Aljaloud et al. [\[37\]](#page-8-0) examined the effect of concentration and radius of copper oxide nanoparticles on the thermal behavior of water/copper oxide nanofluid using MD simulation. Different simulation methods and experimental tests were reported to predict pool boiling characteristics in nanofluids. For instance, Liang et al. [\[38\]](#page-8-0) examined the effect of Fe nanoparticle size on the pool boiling heat transfer using the MD simulation. In another study, Tian et al. [\[39\]](#page-8-0) examined the effect of external force on the pool boiling of Fe/water nanofluid.

On the other hand, previous studies showed that adding an external magnetic field and electric field can improve heat transfer in a micro/ nanochannel. For instance, Wang et al. [\[40\]](#page-8-0) examined the effect of external electric fields on the nanofluid heat transfer. In a review paper, Wang et al. [\[41\]](#page-8-0) examined the effect of external magnetic, and electric fields on nanofluid heat transfer. The results show that adding these external field significantly increased the nanofluid heat transfer. Due et al. [\[42\]](#page-8-0) examined the effect of an external magnetic field on water/ Fe3O4 nanofluid heat transfer.

Besides, the change in HF, density, temperature, and velocity profile of nanoparticles by increasing the external magnetic and external force were studied. For this purpose, the frequency of external magnetic field with different values of 0.01, 0.02, 0.03, and 0.05 1/ps, and the external force with values of 0.001, 0.002, 0.003, and 0.005 eV/ \AA were applied to nanofluid.

2. The MD simulation formulation

The main benefit of computer simulations help understand the properties of molecules in terms of structure and their microscopic interactions. The MD is a simulation method that helps us investigate the system's dynamical properties [\[43\]](#page-8-0). The MD simulation predicts the movements and trajectories of interacting particles over time. This aim was fulfilled by numerical solving the classical Newton's equation of motion [\[44\]](#page-8-0). The numerical solving of Newton's equation was performed using a method called velocity-Verlet integration. The velocity-Verlet algorithm calculated the velocity and the position of a particle in a time step Δt [\[44\].](#page-8-0)

The thermal conductivity and HF of simulated structures were calculated from the Green-Kubo formulation.The Green-Kubo formula is relates the ensemble average of the auto-correlation of the HF to kappa. The HF can be calculated from the fluctuations of per-atom potential and kinetic energies and per-atom stress tensor in a steady-state equilibrated simulation [\[45\].](#page-8-0) Technically, we used 'Compute heat/flux' command in the LAMMPS package witch can calculate the needed HF and describes how to implement the Green_Kubo formalism [\[45\]](#page-8-0). These formulisem are represented as follows (Eqs. (1) and (2)) $[46-48]$:

$$
K = \frac{V}{K_B T^2} \int_0^\infty \langle J_x(0) J_x(t) \rangle dt = \frac{V}{3K_B T^2} \int_0^\infty \langle J(0) J(t) \rangle dt \tag{1}
$$

where, J indicates HF, V indicates the volume, T shows the temperature, and \rm{K}_B represents the Boltzmann constant (1.380649 \times 10⁻²³ m².kg.s⁻². K^{-1}). In the case of two-body interactions, the HF **J** is defined as:

$$
J = \frac{1}{V} \left[\sum_{i} e_i v_i - \sum_{i} S_i v_i \right]
$$

=
$$
\frac{1}{V} \left[\sum_{i} e_i v_i - \sum_{i < j} (F_{ij} \cdot v_j) r_{ij} \right]
$$

=
$$
\frac{1}{V} \left[\sum_{i} e_i v_i - \frac{1}{2} \sum_{i < j} (F_{ij} \cdot (v_i + v_j) r_{ij}) \right]
$$

(2)

where, e_i shows the per-atom energy (potential and kinetic), S_i represents the per-atom stress tensor, v_i represents the particle velocity, F_{ij} is the force exerted on the i and j particles, and V indicates the volume.

The atomic structures simulated in the upcoming research had a defined electric charge from a computational point of view. When the pregnant particle moved in the magnetic field, it always experienced a force that was perpendicular to the field. As a result, greater mobility and velocity will be visible in these samples in the nanochannel. The external magnetic fields were used to atomic samples by following formulations:

$$
B = B_0 \sin(\omega t) \tag{3}
$$

In this equation, B_0 is the amplitude of external magnetic field (0.1) T), and ω is the frequency of this external factor. To study the effect of this external factor on the simulated samples' atomic performance, the external fields' frequencies were 0.01,0.02, 0.03, and 0.05 ps^{-1} .

The most important part of each simulation was to examine the interactions among particles, which were defined via the potential function. Previous studies show that the Lennard-Jones potential function was suitable for modeling ammonia structure. Furthermore, the metallic structure of nanoparticles was used from the EAM potential function [[49,50](#page-8-0)]. This simulation used EAM, Lennard-Jones (LJ), and Columb potential. EAM potential function definition:

$$
U_i = F_{\alpha} \left(\sum_{i \neq j} \rho_{\beta}(r_{ij}) \right) + \frac{1}{2} \sum_{i \neq j} \phi_{\alpha\beta}(r_{ij})
$$
 (4)

where, F_{α} , $\varphi_{\alpha\beta}$, ρ_{β} , and r_{ij} in above equation were the acts as the function of electron density, a pair potential interaction, absorbent force, and the distance among particles, respectively. Alpha (α) and beta (β) are the element types of atoms I and J. LJ potential function is defined as follows [\[51\]](#page-8-0):

$$
U_{LJ} = 4\varepsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] r_{ij} < r_c \tag{5}
$$

where, σ_{ij} and ε_{ij} are the depth of particle potential well, the finite distance in the case the potential was zero. The r_{ii} shows the distance among the particles, and indices i and j represent the element types of atoms I and J. And r_c represents the cutoff radius (12 Å). LJ potential parameters for each present particle in the MD simulation in terms of selective force field are presented in Table 1. These coefficients are written from the UFF and DREIDING references [\[52,53](#page-8-0)].

Due to Table 1, $σ_{ij}$ and $ε_{ij}$ of each particles are calculated using Eqs. (6) and (7) [\[54\]:](#page-8-0)

$$
\varepsilon_{ij} = \sqrt{\varepsilon_i \varepsilon_j} \tag{6}
$$

$$
\sigma_{ij} = \frac{\sigma_i + \sigma_j}{2} \tag{7}
$$

Furthermore, the electric potential energy is described by Coulombic interactions (8) [\[55\]](#page-8-0):

$$
U_{ij} = \frac{Cq_i q_j}{\varepsilon r_{ij}} r_{ij} < r_c \tag{8}
$$

where, C is an energy-conversion constant, q_i and q_j are the charges on the 2 atoms, and ε is the dielectric constant. The cutoff r_c truncates the interaction distance

2.1. The MD simulation process in current research

This research studied pool boiling heat transfer of ammonia nanofluid containing $Fe₃O₄$ nanoparticles in a nanochannel using LAMMPS software. A simulation box with the dimension of $100 \times 60 \times 60$ Å³ was considered in the present simulation. A nanochannel with a thickness of 5 Å was modeled, along with the length of simulation box. This simulated nanochannel is made of Cu particles. One sphere of Fe₃O₄ nanoparticles with a radius of 10 Å was modeled. An example of modeled

Table 1 The LJ parameters in the present MD simulation [[52,53\]](#page-8-0).

Type of Particles	σ_i (Å)	ε_i (kcal/mol)
Cu	3.495	0.005
Н	2.886	0.044
O	3.5	0.06
Fe	4.54	0.055
N	3.995	0.415

structure that included nanochannel and nanofluid is represented in [Figs. 1 and 2](#page-3-0). The initial temperature was set to 195 K using the NVT ensemble. The current simulation consisted of two basic parts. In the first part, using the NVT ensemble, the desired nanostructure reached equilibrium at a temperature of 195 K. To check the equilibration in the structure, the changes in potential energy and total energy were checked (In Supporting Information section). The convergence of these quantities to a constant number showed the equilibrium in the simulated structure. Moreover, the convergence in the mentioned quantities was in terms of appropriate force field. The Nose-Hoover thermostat was used to check the equilibrium in temperature.

3. Result and discussion

3.1. Effects of magnetic field frequency on the atomic and thermal performance of nanostructure

Under the effect of external magnetic field, it had an increasing or decreasing trend. Consequently, it is expected that the boiling of this material in terms of the magnetic field will include various results and phenomena. It will be possible to change the applied external magnetic field in the studied samples via a change in the field amplitude and a change in the frequency of this field. Therefore, the parameters, such as temperature, density, and velocity profile, which were affected by the magnetic field with different frequencies and illustrate various behavior, were analyzed in the current research.

The values of these quantities were measured, and finally averaged in each bin. Finally, the averaged thermophysical parameters were plotted based on the properties of various bins. Therefore, the density profile of studied nanofluid was drawn based on the density of particles in each bin as shown in [Fig. 3](#page-3-0). The 'compute chunk/atom' command was used to calculate the density profile. This compute examined the number of atoms in each bin volume [\[56\].](#page-8-0) As a result, the interactions between the nanochannel walls and the nanofluid particles dominated. Since the studied structure's particle number did not change, it is expected that the density of nanofluid will not change while the external field's frequency changes.

[Fig. 4](#page-3-0) shows the velocity profiles in the desired nanostructure versus increasing the frequency of the external magnetic field. The increase in atomic oscillations in the ammonia-Cu nanofluid was created in terms of the increase in frequency. Therefore, the arrangement of velocity profile and the maximum numerical value of this quantity changed. Quantitative results represent that the maximum velocity of particles was equal to 11.476 Å/fs, which was obtained using the frequency with a magnitude of 0.05 1/ps.

On the other hand, an increase in the amount of movement and mobility of nanoparticles was obtained by increasing the frequency, which will lead to changes in the temperature of atomic structures, according to [Fig. 5.](#page-4-0) [Fig. 5](#page-4-0) shows the temperature profile changes in the nanochannel versus increasing the frequency of magnetic field. By the change in the atomic behavior of studied nanostructure, it is expected that this behavior had a direct effect on the thermal behavior of these nanostructures, so these cases and changes should be considered in the field of the practical application of these atomic samples. The numerical results obtained from this part are fully presented in [Table 2.](#page-4-0)

As mentioned earlier, positive changes in the magnetic field frequency caused the improvement of the oscillatory behavior and the amount of mobility of nanostructures. Therefore, studying the thermal behavior of this nanostructure under new conditions will be important. [Fig. 6](#page-4-0) shows the changes in the amount of HF flowing in the nanochannel versus the increased frequency of magnetic field. In this part, the HF variations are examined in terms of ΔT , where the T variations are equal to:

$$
\Delta T = T_s - T_{sat} \tag{9}
$$

Fig. 1. General representation of the desired nanostructure from a) perspective and b) front view.

Fig. 2. A schematic of a) ammonia/ $Fe₃O₄$ nanofluid and b) $Fe₃O₄$ nanoparticle in the present simulation.

where, T_{sat} and T_s are the saturation T and surface T. As it is well known, the HF diagram exhibits an increase-decrease-increase pattern under the specified conditions, indicating the sample's poolboiling hear transfer procedure. Based on the results presented in [Fig. 6](#page-4-0), increasing the frequency of external magnetic field led to an increase in the HF transferred in the nanochannel.

As the temperature increased, these bubbles joined together and reduced the heat transfer (more details in [Section 5.2](#page-7-0) (Boiling Curve)). As the bubbles' size increased, the fluid's density decreased [\[57\].](#page-8-0) [Fig. 7](#page-4-0) shows the density profile changes before and after the critical heat flux in the presence of a magnetic field with 0.01 1/ps frequency magnitude. Numerically, the maximum density of particles was equal to 0.1405 and 0.1277 atom/ \AA^3 before and after the critical heat flux. This decrease in density was in terms of the formation of bubbles on the surface of fluid.

In the discussion of time series, there was a dependence among the observations based on time. Since in statistics, dependence is often expressed as correlation, and the word autocorrelation means serial correlation or dependence among the sequential values in terms of time. [Fig. 8](#page-4-0) represents the change in heat flow autocorrelation function (HFAF) of the simulated structure over the timestep. This chart was

descending in order of delay. The longer the observations were delayed, the less correlation they found. Fig. 8 show that the HFAF condensation of the simulated structure converged to zero with oscillating performance. Following Green-Kubo equation, the HFAF convergence to zero showed thermal conductivity convergence [\[58\]](#page-8-0).

Fig. 9 and [Table 3](#page-5-0) show the changes in thermal conductivity with the increased frequency of magnetic field. The previous studies showed that by increasing the magnetic field magnitude, the thermal conductivity showed an upward behavior [\[59](#page-8-0)–61]. This increase was due to the increase in the velocity and movement of the particles with the increase in

Frequency of magnetic field	$0.01(1/\text{ps})$	0.02 (1/ps)	$0.03(1/\text{ps})$	$0.05(1/\text{ps})$
Thermal	0.813 (W/	0.821 (W/	0.854 (W/	0.866 (W/
Conductivity	$m.K$)	$m.K$)	$m.K$)	$m.K$)

the magnitude of magnetic field. Generally, applying a magnetic field leads to a change in the direction of the particles in the magnetic nanofluid. This change in direction leads to an increase in the energy and acceleration of the particles. So, the magnetic field itself does not change the velocity of the particles [\[62\].](#page-8-0)The higher the velocity of the particles, the more they collide, so heat transfer occurred at a higher rate. In general, as the frequency increased, the energy of the particles increased. Energy determines the reaction rate factor. Therefore, by increasing energy, the velocity and movement of particles improved. Moreover, the temperature of particles increased [\[63\]](#page-8-0). Therefore, it can be said that the with increasing the magnetic field magnitude, the particles are accelerated [\[64\].](#page-8-0) As more charge is put in more motion, the better the thermal behavior of the magnetic nanofluid [\[65\]](#page-8-0). Previous studies reported thermal conductivity for ammonia fluid in the range from 0.7 to 0.8 W/m.K [\[66\].](#page-8-0)

3.2. The effect of external force on the atomic and thermal behavior of nanostructure

The external force applied from the surrounding environment to desired nanostructure is an important and influential factor. Therefore, to check this factor in this section, different amounts of external force with values of 0.001, 0.002, 0.003, and 0.005 eV/ \AA were used to the nanostructure as shown in Fig. 10. Considering in this simulation, the composition of studied nanostructures didn't change due to the atomic ratio of $Fe₃O₄$ nanoparticles to ammonia fluid particles, the density value in these nanostructures did not change significantly. This change is due to the increase of disturbances related to the bubbles created on the surface of the fluid by increasing the external force. The lack of density change is due to the constant atomic ratio of $Fe₃O₄$ nanoparticles to ammonia fluid particles, so the density value does not change much in these atomic nanostructures.

Fig. 11 illustrates the fluctuations in the velocity according to the increase of external force applied to the nanofluid. Studying the velocity profile is very important to survey the thermal performance of desired

Fig. 11. Changes in nanofluid velocity profile vs. increasing external force.

nanostructures. As shown in Fig. 11, the velocity values increase with the external pressure applied to the nanofluid. Numerically, with the increase of external force to 0.005 eV/Å, the velocity of particles reached from 6.977 Å/fs to 13.939 Å/fs. Increasing the external force in the simulated atomic structure increased the mobility of the particles in the nanochannel increases. As a result, the maximum velocity in the nanofluid particles increases. Thus, it can be found that the thermal performance of nanofluids is improved due to such changes.

Fig. 12 shows the changes in the temperature of nanofluid according to the increase of the external force. Numerically, with the increase of external force, the maximum temperature value increased from 398.42 K to 794.61 K. An increase in the pressure applied to the nanostructure was obtained as a result of an increase in the external force. The results of this part are presented in [Table 4.](#page-6-0)

The progress of the thermal performance with the increased external force had a direct relationship with the HF in desired nanostructures. HF in the nanostructure is reported in [Fig. 13](#page-6-0). Besides, when the external force increased, the pressure on the nanofluid increased. It causes the velocity of nanofluid particles to increase, and HF was transferred with greater intensity and quantity.

[Fig. 14](#page-6-0) and [Table 5](#page-6-0) show the changes in thermal conductivity with the increase in external force. By increasing this thermodynamic quantity, it is expected that the heat transfer in the atomic structure will

increase. Finally, the thermal conductivity will increase in the studied samples. Therefore, the structure's thermal resistance decreased with the external force increase.

The obtained results show that adding the external force had a better thermal performance than the magnetic field in the studied structure. Therefore, to improve the thermal performance of studied structure in various industries, an external force can be applied in addition to applying a magnetic field.

4. Conclusion

The current paper analysed the pool boiling process in ammoniabased nanofluid using the MD simulation and LAMMPS software. The ammonia/Fe3O4 nanofluid pool boiling process was carried out in a Cu nanochannel. In general, the processes carried out in this research were checked in the two-step, including the equilibration and the investigation of atomic structures' atomic and thermal behavior. In the first step, the equilibrium in the nanostructure was checked. The results showed that:

- The potential energy in the desired nanostructure converged to a − 22,451.3 eV after 20 ns passed.
- The amount of total energy in desired nanostructure, which is the sum of the kinetic and potential energies of the nanostructure, converged to a $-22,532.3$ eV.

In the second step, parameters, such as temperature, velocity, density, and HF of nanostructure were evaluated. The results indicated that:

- Increasing the frequency of external magnetic field from 0.01 1/ps to 0.05 1/ps led to the convergence of velocity and temperature profiles to the numerical values 11.476 Å/fs and 410.07 K.
- The results show that with the increase in the magnetic field frequency (from 0.01 to 0.05 ps^{-1}), the thermal conductivity in the nanofluid increased from 0.813 to 0.866 W/m.K .Consequently, the thermal resistance in the structure decreased. HF increased with increaseng in the external field frequency.
- Increasing the external force to 0.005 eV/ \AA led to the velocity and temperature profiles increase to 13.939 Å/fs and 794.61 K.
- The results show that an increase in external force led to an increase in HF. By increasing the external force from 0.001 to 0.005 $eV/\text{\AA}$, thermal conductivity in the nanofluid increased from 0.850 to 1.06 W/m.K.

5. Supporting information

5.1. Equilibrium process

The simulated sample's equilibration time equals 20 ns. Fig. 15 shows the potential energy changes for nanofluid in 20 ns. The results

Fig. 15. Potential energy versus time in the presence of nanofluid.

obtained for the potential energy of the desired nanostructure reveal that after 20 ns, this quantity's value approaches negative values. This convergence to a constant value showed sufficient simulation time for the equilibration process. Numerically, the potential energy converged to a value of − 22,451.3 eV. The negative value of the potential function showed that the simulated nanostructure had good stability and the attraction force prevails among the existing particles. Convergence in the potential energy of the simulated structure was in terms of appropriate force field. The more negative the potential energy, the more stable the simulated structure.

One of the other important cases studied to determine the behavior of the nanostructure is the total energy. The mentioned quantity accurately predicts the atomic behavior of nanostructure in the subsequent times of simulation. Fig. 16 shows the changes in the total energy for nanofluid after 20 ns. According to the results in $Fig. 16$, the total energy value in the simulated metal nanochannel with the presence of base fluid approached the numerical value of − 22,532.3 eV.

5.2. Boiling curve

Nukiyama studied different areas of pool boiling using a nickelchrome wire placed in a water reservoir [\[67\].](#page-8-0) The heat flux from the nickel-chrome wire to the saturated water was determined by measuring the current intensity and the potential difference. The temperature of wire was obtained from the property of its electrical resistance changes with temperature. According to the diagram below (see Fig. 17), pool boiling had four different regimes.

• **Free Convection Boiling**

Hence, bubbles are not produced, and the free movement mechanism mostly does heat transfer.

• **Nucleate Boiling**

Separate bubbles were formed in this area. By increasing the temperature in this area, the bubbles joined together, and considering the liquid was heated, the bubbles can reach the free surface of the liquid and not be distilled in the liquid. This heat flux is called critical heat flux.

• **Transition boiling**

As the temperature increased further, bubbles accumulated around the joint surface. These bubbles coalesce and reduce heat transfer. Because bubbles contain gas, which had a much lower conductivity than liquid, there will be the lowest heat flux in this temperature difference. This point is called Leidenfrost Point

• **Film Boiling**

The bubble coalition will be eventually broken, large vapor bubbles will be pulled from the surface, and the heat flux will increase by increasing temperature.

6. Future outline

In future studies, multi-particle collision dynamics (MPCD) or MPCD-MD hybrid method methods can be used to study better the process of particle movement, and thermal conductivity of nanofluid. The hybrid method of MPCD-MD will be used to study the effect of aggregation morphology on the thermal conductivity of different nanofluids [[69,70\]](#page-8-0). Therefore, to validate and study more precisely the studied particles' behavior, this hybrid method can be used.
